Autoimmune Hemolytic Anemia in Patients with Systemic Lupus Erythematosus

Styliani I. G. Kokori, MD, John P. A. Ioannidis, MD, Michalis Voulgarelis, MD, Athanasios G. Tzioufas, MD, Haralampos M. Moutsopoulos, MD

PURPOSE: We sought to evaluate the clinical and serologic associations with, and outcomes of, autoimmune hemolytic anemia, as compared with other types of anemia, in patients with systemic lupus erythematosus (SLE).

SUBJECTS AND METHODS: We studied 41 consecutive patients with SLE with clinically manifest autoimmune hemolytic anemia, including 27 (66%) in whom hemolysis was the initial disease manifestation. We matched each patient for age and disease duration with a patient with SLE with anemia resulting from a different cause.

RESULTS: The 41 patients had a total of 50 episodes of autoimmune hemolytic anemia. The recurrence rate was 4 per 100 person-years. Cases and controls had similar mean (± SD) lupus activity indexes (2.1 ± 1.5 vs 2.4 ± 1.3, $P = 0.5$). Patients with autoimmune hemolytic anemia at any time could be distinguished from patients with other causes of anemia, because they were more likely to have elevated titers of IgG anticardiolipin antibodies (odds ratio (OR) = 5.8; 95% confidence interval (CI), 1.4 to 24) and thrombosis (OR = 4.6; 95% CI, 1.0 to 21). Autoimmune hemolytic anemia at the onset of SLE was independently associated with renal involvement (OR = 5.4; 95% CI, 1.0 to 28), thrombocytopenia (OR = 7.3; 95% CI, 1.1 to 48), and possibly thrombotic episodes during follow-up (OR = 11; 95% CI, 0.8 to 160) when compared with controls with other types of anemia at the onset of SLE.

CONCLUSIONS: Autoimmune hemolytic anemia usually occurs at the onset of SLE, and its recurrence rate is low among treated patients. The association with IgG anticardiolipin antibodies and thrombosis suggests that the occurrence of autoimmune hemolytic anemia may define a subgroup of patients with SLE who have characteristic serologic and clinical manifestations. Am J Med. 2000;108:198–204. ©2000 by Excerpta Medica, Inc.

Patients with systemic lupus erythematosus (SLE) may develop several hematologic complications, including anemia, leukopenia, and thrombocytopenia (1,2). Anemia can have many causes, including autoimmunity (3,4). Several case series (5–11) have shown that autoimmune hemolytic anemia occurs in approximately 10% of patients with SLE. It may be the sole presenting sign of the disease and may predate the appearance of other disease manifestations by several years (3). Autoimmune hemolytic anemia can also be part of the antiphospholipid syndrome, which is associated with high titers of anticardiolipin antibodies, thrombosis, thrombocytopenia, and recurrent fetal loss (12).

However, the clinical importance and the clinical and serologic associations of autoimmune hemolytic anemia in SLE are controversial. There is substantial uncertainty about whether hemolysis portends a more severe (9,13) or more benign (6,8) prognosis. Moreover, the effects of, and risk factors for, autoimmune hemolytic anemia have not been evaluated using controls with SLE who have other types of anemia. Hence, the aim of this study was to evaluate the clinical and serologic associations with, and prognosis of, patients with SLE and autoimmune hemolytic anemia. From within a large cohort of consecutive patients with SLE, we identified those with autoimmune hemolytic anemia and compared them with patients with other types of anemia.

MATERIAL AND METHODS

Patients were seen at the Department of Pathophysiology, School of Medicine, National University of Athens, from November 1994 to October 1998. All patients fulfilled at least four of the revised American College of Rheumatology criteria for the diagnosis of SLE (14). We considered patients to have active autoimmune hemolytic anemia if they had a decrease of at least 3 g/dL in their hemoglobin level, an increase in the serum unconjugated bilirubin level of at least 0.6 mg/dL, a reticulocyte count of 5% or greater corrected for hemoglobin levels, and a positive direct Coombs' test by direct antiglobulin test using polyspecific anti–human immunoglobulin and anticomplement antibodies (Ortho Diagnostics, Inc, Raritan, New Jersey). We also required that other causes of hemolysis, including hereditary, drug-induced, microangiopathic hemolytic anemia, had been excluded.

We identified patients who developed autoimmune hemolytic anemia at the onset of SLE, or in whom it oc-

Evans syndrome (ES) is a rare disease characterized by the simultaneous or sequential development of autoimmune hemolytic anemia (AIHA) and immune thrombocytopenia (ITP) and/or immune neutropenia. To better describe the characteristics and outcome of ES in adults, a survey was initiated in 2005. The data from 68 patients (60% of them women) fulfilling strict inclusion criteria for ES are reported. The mean age at time of ITP and/or AIHA onset was 52 plus or minus 33 years, both cytopenias occurred simultaneously in 37 cases (54.5%). ES was considered as "primary" in 34 patients (50%) but was associated with an underlying disorder in half of the cases, including mainly systemic lupus, lymphoproliferative disorders, and common variable immunodeficiency. All patients were given corticosteroids, but 50 of them (73%) required at least one "second-line" treatment, including splenectomy(n = 19) and rituximab (n = 11). At time of analysis, after a mean follow-up of 4.8 years, only 22 patients (32%) were in remission off treatment; 16 (24%) had died. In elderly patients, the risk of cardiovascular manifestations related to AIHA seems to be higher than the ITP-related risk of severe bleeding. In conclusion, ES is a potentially life-threatening condition that may be associated with other underlying autoimmune or lymphoproliferative disorders. (Blood. 2009;114:3167-3172)

Introduction

Evans syndrome (ES), which was first described in 1951, is an autoimmune disorder characterized by the simultaneous or sequential development of autoimmune hemolytic anemia (AIHA) and immune thrombocytopenia (ITP) and/or immune neutropenia in the absence of any underlying cause.[1] Although ES has been since its first description considered or defined as an "idiopathic" condition and thus mainly as a diagnosis of exclusion, ES may be associated with or show other diseases or conditions such as systemic lupus erythematosus (SLE),[2] lymphoproliferative disorders,[3,4] or primary immunodeficiencies.[5] In childhood, ES may also show an autoimmune lymphoproliferative syndrome (ALPS), a disorder of disrupted lymphocyte homeostasis related to some mutations in the Fas apoptotic pathway.[6] ES is a rare condition because it is diagnosed in only 0.8% to 3.7% of all patients with either ITP or AIHA at onset.[7] Few and mainly pediatric data on ES are available in the literature[8-11]; therefore, the characteristics and outcome of adult's ES are poorly known. Moreover, because there have been no prospective or randomized controlled trials, the management of ES is based on empirical data, and it is mainly based on indirect evidence extrapolated from the "standard of care" in primary ITP or AIHA or both.

To better define the clinical spectrum of ES in adults and to describe the main characteristics and outcome of this rare condition, a survey was initiated in 2005 throughout the Working Group on Thrombocytopenias of the European Hematology Association. The data of 68 cases of ES included in this registry are reported here.

Methods

Patients

This retrospective cohort study was initiated in the department of Internal Medicine at Henri Mondor University Hospital (Créteil, France), a tertiary national referral center for adult autoimmune cytopenias. The study was then extended to 7 other centers in France (n = 5 departments of internal medicine) and Italy (n = 4 departments of hematology-oncology) throughout the Working Group on Thrombocytopenias of the European Hematology Association.

All consecutive patients with the diagnosis of ES in 1 of the 8 participating centers over a 15-year period and fulfilling the following eligibility criteria were included: age 16 years or more at diagnosis; ES defined by the occurrence (either simultaneously or sequentially within at least a 10-year period of time) of AIHA and ITP or autoimmune neutropenia. AIHA was defined by a hemoglobin (Hb) level of 11 g/dL or less at diagnosis with features of hemolysis (low haptoglobin level and/or increased LDH and/or bilirubin level) and a positive direct antiglobulin test (DAT) or when the DAT was negative, after the exclusion of any other cause of acquired or hereditary hemolytic anemia. ITP was defined according to American Society of Hematology criteria,[12] and only patients with a platelet count below 100 × 10⁹/L on 2 separate occasions were included. In case of concomitant active AIHA, the presence of a mild splenomegaly was not an

Drug induced immune haemolytic anemia in the Berlin Case-control surveillance study

Garbe et al, Br J Haematol, 2011; 154: 644-53

assessment of individual cases. The spectrum of drugs suspected to cause IHA is similar to that reported in the literature (Salama *et al*, 1996). In principle, any drug may induce IHA. In each case of newly diagnosed IHA a drug aetiology should be considered and a careful history of medication must be taken.

Summary

Drug-induced immune haemolytic anaemia is a rare but serious condition. This study investigated the possibility of drug aetiology of immune haemolytic anaemia (IHA) in 134 patients with new onset of IHA who were identified in the Berlin Case-Control Surveillance Study between 2000 and 2009. Single drugs related to IHA in three or more patients and assessed more than once as a certain or probable cause of IHA in a standardized causality assessment included diclofenac, fludarabine, oxaliplatin, ceftriaxone and piperacillin. In a case-control study including all 124 IHA cases developed in outpatient care and 731 controls, significantly increased odds ratios (OR) were observed for beta-lactam antibiotics (OR = 8·8; 95% confidence interval [CI] 3·2–25·2), cotrimoxazole (OR = 6·5; CI 1·1–37·9), ciprofloxacin (OR = 6·9, CI 1·3–38·3), fludarabine (OR = 22·2; CI: 2·8–454·5) and lorazepam (OR = 5·3; CI: 1·2–21·2). Excluding new onset cases with a chronic IHA disease course, an increased risk became also apparent for diclofenac with an OR of 3·1 (CI 1·3–7·0). This is the first case-control study investigating drugs as risk factors for IHA. It corroborates an increased risk for several drugs that have been implicated as a cause of IHA in the standardized causality assessment of individual cases.

Keywords: Berlin case-control surveillance study, immune haemolytic anaemia, drug-induced, causality assessment, case-control study.

Drug-induced immune haemolytic anaemia (DIIHA) is a serious, but rare condition with an estimated incidence of approximately one case per million inhabitants per year (Petz & Garratty, 2004). A substantial number of fatal cases have been described in case reports, case series and reviews (Garratty et al. 1991, 1992; Meyer et al. 1999; Seltsam & Salama, 2000; Ahrens et al, 2002; Garratty, 2010; Yürek et al, 2010). Both the antidepressant nomifensine and the liver protectant clanidanol have been withdrawn from the market because of their implication in DIIHA (Salama, 2009). DIIHA

Mortality in the Catastrophic Antiphospholipid Syndrome

Causes of Death and Prognostic Factors in a Series of 250 Patients

Silvia Bucciarelli,[1] Gerard Espinosa,[1] Ricard Cervera,[1] Doruk Erkan,[2] José A. Gómez-Puerta,[1] Manuel Ramos-Casals,[1] Josep Font,[1] and Ronald A. Asherson,[3] for the CAPS Registry Project Group (European Forum on Antiphospholipid Antibodies)

Table 4. Laboratory features of patients with CAPS, categorized according to their death or survival*

	Patients who died during a CAPS episode (n = 114)	Patients who survived a CAPS episode (n = 136)
Disseminated intravascular coagulation	15/90 (16.7)	18/131 (13.7)
Hemolysis	33/101 (32.7)	42/119 (35.3)
Thrombocytopenia (≤100,000 platelets/mm^3)	34/86 (39.5)	54/101 (53.4)
Schistocytes	9/78 (11.5)	20/108 (18.5)
Antinuclear antibodies	62/94 (65.9)†	56/114 (49.1)
Antiphospholipid antibodies		
IgG aCL	87/103 (84.5)	110/133 (82.7)
IgM aCL	35/92 (38)	57/129 (44.2)
Lupus anticoagulant	78/97 (80.4)	95/126 (75.4)

* Values are the number of patients/number tested (%). CAPS = catastrophic antiphospholipid syndrome; aCL = anticardiolipin antibodies.
† $P = 0.017$ versus the group that survived.

ABSTRACT

Paroxysmal nocturnal hemoglobinuria is a rare, acquired disease associated with hemolytic anemia, bone marrow failure, thrombosis, and, frequently, poor quality of life. The International PNH Registry is a worldwide, observational, non-interventional study collecting safety, effectiveness, and quality-of-life data from patients with a confirmed paroxysmal nocturnal hemoglobinuria diagnosis or detectable paroxysmal nocturnal hemoglobinuria clone, irrespective of treatment. In addition to evaluating the long-term safety and effectiveness of eculizumab in a global population, the registry aims to improve diagnosis, optimize patient management and outcomes, and enhance the understanding of the natural history of paroxysmal nocturnal hemoglobinuria. Here we report the characteristics of the first 1610 patients enrolled. Median disease duration was 4.6 years. Median granulocyte paroxysmal nocturnal hemoglobinuria clone size was 68.1% (range 0.01-100%). Overall, 16% of patients had a history of thrombotic events and 14% a history of impaired renal function. Therapies included anticoagulation (31%), immunosuppression (19%), and eculizumab (25%). Frequently reported symptoms included fatigue (80%), dyspnea (64%), hemoglobinuria (62%), abdominal pain (44%), and chest pain (33%). Patients suffered from poor quality of life, 28% of patients had been hospitalized due to paroxysmal nocturnal hemoglobinuria-related complications and 17% stated that paroxysmal nocturnal hemoglobinuria was the reason they were not working or were working less. This international registry will provide an ongoing, valuable resource to further the clinical understanding of paroxysmal nocturnal hemoglobinuria. (*Clinicaltrials.gov identifier:01374360*)

Introduction

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare, acquired disease characterized by chronic intravascular hemolysis caused by uncontrolled complement activation. The cellular abnormality in this life-threatening disease originates from a mutation in the phosphatidylinositol glycan class A (*PIGA*) gene, resulting in a deficiency of glycosylphosphatidyl inositol (GPI)-anchored complement regulatory proteins, including CD55 and CD59, on the surface of blood cells.[1] Patients with chronic hemolysis experience a marked increased risk of thromboembolism (TE), which may ultimately lead to target organ damage and death.[2,3] Retrospective analyses have reported that, despite best supportive care, the 10-year survival rate in patients with PNH ranged from 50% for patients diagnosed between 1940 and 1970[4] to 75% in a more recent series.[5] TE is the leading cause of mortality in patients with PNH, accounting for between 40% and 67% of deaths with known causes.[6] Patients with PNH also experience symptoms including fatigue, abdominal pain, headache, shortness of breath, dysphagia, and erectile dysfunction.[7] These symptoms can be debilitating and significantly reduce the quality of life (QoL) of patients with PNH.[8] PNH may develop in the absence of another bone marrow disorder (BMD), as a condition secondary to BMDs such as aplastic anemia (AA) or myelodysplastic syndrome, or as subclinical PNH.

The only potentially curative therapy for PNH is allogeneic bone marrow transplantation; however, this procedure is associated with substantial morbidity and mortality[9,10] and, consequently, is not an appropriate therapeutic option for most patients. Historically, management of PNH was limited to the use of supportive measures such as blood transfusions and anticoagulation therapy. However, it has been reported that the risk of TE in patients with PNH remains high even in patients who have no clinical evidence of TE or are receiving prophylactic anticoagulation,[11] which is itself associated with an increased risk of bleeding complications.[12] In one

Enzymopathies

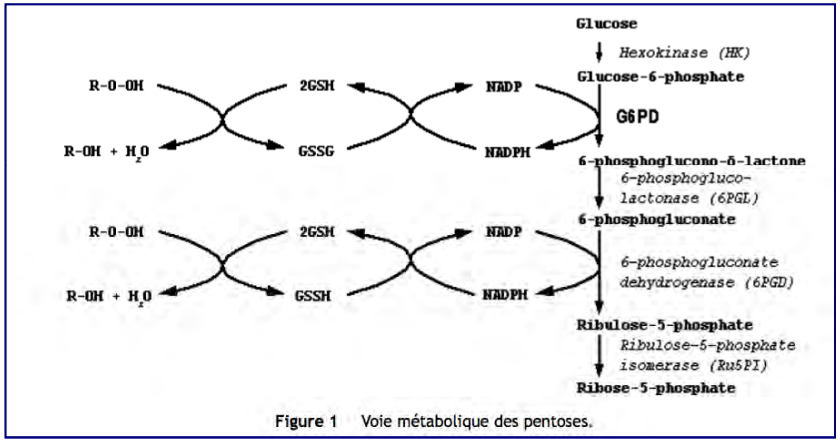

Figure 1 Voie métabolique des pentoses.

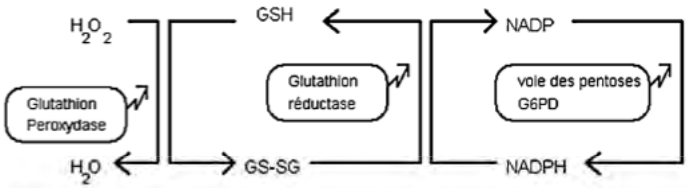

GSH : glutathion réduit
GSSG : glutathion oxydé

Figure 2 Métabolisme du gluthation : la glucose-6-phosphate déshydrogénase (G6PD) est l'enzyme centrale de la cascade antioxydante du globule rouge. Le gluthation détoxifie la cellule des molécules de peroxyde d'hydrogène grâce à la gluthation peroxydase. Le gluthation ainsi oxydé est recyclé par la glutha-tion S-transférase et la gluthation réductase. La nicotinamide adénine dinucléotide phosphate réduite (NADPH) permettant la réduction du gluthation est fournie grâce à la voie des pentoses et donc à la G6PD. Le ratio gluthation oxydé (GSSG)/gluthation réduit (GSH) est de 100/1.

Résumé. Nous rapportons l'observation d'un homme de 59 ans présentant une anémie microcytaire hypochrome régénérative. Les explorations ont révélé la présence d'une hémoglobine H, tétramère de β-globine, qui suggère un trouble de synthèse de l'α-globine et donc une α-thalassémie. L'absence d'antécédents personnels et familiaux ainsi que la présence d'une aniso-poïkilocytose marquée sur les frottis sanguins associée à une nette surcharge en fer (ferritinémie supérieure à 1 500 µg/L) ont fait évoquer un syndrome myélodysplasique. Celui-ci a effectivement été confirmé par un examen médullaire avec notamment des signes marqués de dysérythropoïèse. Ce tableau clinique est compatible avec le syndrome ATMDS (*acquired α-thalassemia-myelodysplastic syndrome*). Une centaine de cas est recensée dans le monde et un registre international existe depuis le début des années 1980. L'origine de ce syndrome est méconnue, des délétions du génome α ont été évoquées, mais depuis peu, il semble que le gène *ATRX* soit fréquemment impliqué dans la pathogenèse. Ce gène, situé sur le bras long du chromosome X, code pour une protéine associée à la chromatine qui régule la transcription de certains gènes. Les gènes α seraient une des cibles de cette protéine.

Mots clés : *syndrome ATMDS, hémoglobine H, dysérythropoïèse, α-thalassémie acquise, myélodysplasie, hémochromatose secondaire*

Abstract. We report the case of a 59 year old man presenting a regenerative microcytic hypochromic anaemia. The investigations revealed the presence of haemoglobin H, suggesting abnormalities in the α-globin chains synthesis. Alpha-thalassemia was thus suspected. The patient had no personal or familial history. The association with aniso-poïkilocytosis and a marked iron overload (ferritinemia > 1 500 µg/L) suggested a myelodysplastic syndrome, which was confirmed with a bone marrow aspiration. The pattern was consistent with the Acquired α-Thalassemia-Myelodysplastic Syndrome (ATMDS). About a hundred cases are listed worldwidely and collected in an international registry. The causes of ATMDS are ignored, but recent reports indicate that the *ATRX* gene may be implicated in the pathogenesis. ATRX is a chromatin-associated protein, involved in the transcription of several genes. The α globin genes could be one of the targets of the ATRX protein.
